*(Received December 5, 2014, Revised January 10, 2015, Accepted January 11, 2015)*

**Abstract.** This study aims to propose a Bayesian approach to consider changes in temperature and vehicle weight as environmental and operational factors for vibration-based long-term bridge health monitoring. The Bayesian approach consists of three steps: step 1 is to identify damage-sensitive features from coefficients of the auto-regressive model utilizing bridge accelerations; step 2 is to perform a regression analysis of the damage-sensitive features to consider environmental and operational changes by means of the Bayesian regression; and step 3 is to make a decision on the bridge health condition based on residuals, differences between the observed and predicted damage-sensitive features, utilizing 95% confidence interval and the Bayesian hypothesis testing. Feasibility of the proposed approach is examined utilizing monitoring data on an in-service bridge recorded over a one-year period. Observations through the study demonstrated that the Bayesian regression considering environmental and operational changes led to more accurate results than that without considering environmental and operational changes. The Bayesian hypothesis testing utilizing data from the healthy bridge, the damage probability of the bridge was judged as no damage.

**Keywords:** long-term bridge monitoring; Bayesian regression; temperature; vehicle weight; vibration

## 1. Introduction

Maintaining and improving civil infrastructures including bridge structures are keen technical issues in many countries. Developing an effective maintenance strategy relies on a timely decision on the health condition of the structure. Structural health monitoring (SHM) using vibration data thus has been recognized as one of the promising technologies for providing a timely decision on the bridge health condition. Most precedent studies on SHM specifically examine changes in modal properties of structures (e.g., Doebling *et al.* 1996). The fundamental concept of this technology is that modal parameters are functions of structures' physical properties. Therefore, a change in physical properties, such as reduced stiffness resulting from damage, will detectably change these modal properties. In fact, many techniques to identify the hidden information of structural integrity in the vibration data have been proposed to diagnose bridge structures

(Deraemaeker *et al.* 2007, Dilena and Morassi 2011 and Kim *et al.* 2012). However, real bridge structures are subject to changing environmental and operational conditions that affect structural integrity information during the long in-service period. Some components in the signals affected by those environmental and operational effects lurk in the measured vibration data and disguise themselves as structural responses (Sohn *et al.* 2003, and Deraemaeker *et al.* 2007). As in-service effects on vibration monitoring of bridges, temperature, wind-induced and traffic-induced vibrations and traffic mass effects are factors to be considered. Focusing on short and medium span bridges, however, temperature and traffics are dominant factors affecting the vibration of bridges (Peeters and De Roeck 2001, and Cunha *et al.* 2013). Therefore, how to consider those environmental and operational effects in long-term bridge health monitoring is a crucial issue.

This study is intended to investigate a way to consider time-varying temperature and vehicle weight as environmental and operational factors for long-term vibration-based bridge health monitoring (BHM) by means of a Bayesian approach, which is an improvement from previous researches considering only temperature as an environmental factor by Kim *et al.* (2011, 2013a).

The proposed Bayesian approach consists of three steps. Step 1 is to identify damage-sensitive features (damage indicators, DIs) from coefficients of the auto-regressive (AR) model utilizing bridge accelerations (Nair *et al.* 2006, Kim *et al.* 2012, 2013b). Since AR coefficients are closely linked with features of bridge vibrations, the DI changes due to changes in the bridge health condition as well as environmental and operational conditions during the monitoring campaign. Step 2 is to perform a regression analysis of the DIs identified in step 1 (observed DIs ( $DI_{ob}$ 's)) to consider environmental and operational changes by means of the Bayesian regression (Kitagawa and Gersch 1984). The Bayesian regression is useful to examine long-term monitoring data effectively by online updating. Step 3 is to make a decision on the bridge health condition based on residuals utilizing 95% confidence interval and the Bayesian hypothesis testing (Sankararaman and Mahadevan 2011). The residuals are differences between the  $DI_{ob}$ 's and the DI predicted by means of the Bayesian regression in step 2 (predicted DIs ( $DI_{pr}$ 's)).

The Bayesian approach is applied to investigate monitoring data of an in-service bridge. The data were measured at a seven-span plate-Gerber bridge recorded over a one-year period. This study considers time-varying temperature and vehicle weight as environmental and operational factors respectively. Vehicle weights are identified utilizing a bridge weigh-in-motion (BWIM) system (Moses 1979 and Heng *et al.* 2011) installed on the bridge. All the data is taken from the healthy bridge, since no damage and deterioration was reported during the monitoring period. The influence of time-varying environmental and operational factors is investigated by comparing three cases: Case 1 is to utilize acceleration, temperature and vehicle weight data considering temperature and vehicle weight as environmental and operational factors; Case 2 is to utilize acceleration and temperature data considering temperature as environmental factor; and Case 3 is to utilize only acceleration data without considering environmental and operational changes.

## 2. A Bayesian approach for long-term BHM to consider environmental changes

### 2.1 Identification of damage-sensitive features from AR coefficients: step 1

Many studies focus on changes in system frequencies and structural damping constants for the structural diagnosis of bridges by utilizing a linear time series model such as the AR model (e.g., Kim *et al.* 2012, 2013c). However, there exist drawbacks in modal parameter-based bridge

diagnosis using time series models; e.g., the optimal time series model for vibration responses of bridge structures usually comprises a higher-order term, and as a result the optimal model identifies even spurious modal parameters, which causes false system frequencies and damping constants. Those false modal parameters make it difficult to choose the proper modal parameters affected by structural damage. The drawback of the classical method is the driving force behind this study. This study considered an alternative parameter based on AR coefficients as a damage-sensitive feature for the vibration-based BHM because both system frequency and damping constant are related to AR coefficients.

Step 1 is to identify the  $DI_{ob}$  from coefficients of the AR model of bridge acceleration responses. This paper includes only a brief description about the DI without covering details, since theoretical backgrounds of utilizing AR coefficients as a damage-sensitive feature have already investigated by Nair *et al.* (2006) for a model building structure and by Kim *et al.* (2013b, 2013c) for a model bridge and thus details can be fully accessed in the studies.

Linear dynamic system can be idealized using the AR model shown in Eq. (1) (Kim *et al.* 2012, 2013c).

$$z_k = \sum_{i=1}^p a_i z_{k-i} + e_k \tag{1}$$

where  $z_k$  denotes the  $k$ -th output of a system,  $a_i$  is the  $i$ -th AR coefficient,  $p$  is the optimal AR order and  $e_k$  indicates the  $k$ -th error. The optimal AR order, which is obtainable by means of Akaike Information Criteria (AIC) (Akaike 1974), is used in this study. AIC is given by Eq. (2)

$$AIC = n \log(2\pi E^2) + 2(m + 1) + n \tag{2}$$

where  $n$  indicates the number of data,  $m$  represents AR order, and  $E^2$  means square of prediction error. The AIC consists of two terms; the first term is a log-likelihood function and the second term is a penalty function for the number of the AR order.

The  $DI_{ob}$  is defined by Eq. (3) (Nair *et al.* 2006 and Kim *et al.* 2013c).

$$DI_{ob} = \frac{|a_1|}{\sqrt{a_1^2 + a_2^2 + a_3^2}} \tag{3}$$

where  $a_1$ ,  $a_2$  and  $a_3$  indicate the first, second and third AR coefficients respectively. Since the AR coefficients are closely linked with bridge vibrations, the  $DI_{ob}$  changes due to changes in bridge health condition as well as environmental and operational conditions. Nair *et al.* (2006) showed that the first three AR coefficients are the most significant among all the coefficients of the AR model utilizing data from the laboratory experiment on a model building. Kim *et al.* (2013b) also observed that the  $DI_{ob}$ , considering up to the third order of the AR coefficients, is a promising parameter in bridge health monitoring, since the  $DI_{ob}$  is observed to be the most sensitive to damage through a bridge-moving vehicle laboratory experiment.

## 2.2 Regression analysis to consider environmental changes by Bayesian regression: step 2

### 2.2.1 Introduction

In a long-term bridge monitoring, the  $DI_{ob}$  varies due to time-varying environmental and operational conditions. This study adopts the Bayesian regression to cope with influences of these time-varying environmental and operational conditions on the  $DI_{ob}$ 's. The idea is to predict DIs ( $DI_{pr}$ ) considering environmental and operational effects in a regression model. If  $DI_{pr}$  are comparable with  $DI_{ob}$ 's then the residual that is the difference between the  $DI_{pr}$  and  $DI_{ob}$  will be small enough. In other words the residuals are fitted within a confidence interval statistically. Therefore this study monitors statistical changes of residuals of newly observed  $DI_{ob}$ 's. If the residual of the  $DI_{ob}$ 's crosses a confidence level, it can be treated as a potential anomaly.

Step 2 is to perform a regression analysis of the  $DI_{ob}$ 's identified in the step 1 to consider influences from environmental and operational factors by means of the Bayesian regression as an online updating method (Kitagawa and Gersch 1984).

### 2.2.2 Bayesian regression algorithm

The state space model for the Bayesian regression is given by Eqs. (4) and (5).

$$\mathbf{x}_t = \mathbf{F}\mathbf{x}_{t-1} + \mathbf{G}\mathbf{v}_t \quad (4)$$

$$y_t = \mathbf{H}_t\mathbf{x}_t + w_t \quad (5)$$

where  $\mathbf{x}_t$  and  $y_t$  are the state matrix and observation at a time  $t$  respectively.  $\mathbf{v}_t$  and  $w_t$  denote noise at  $t$ . For any particular model of the time series,  $\mathbf{F}$ ,  $\mathbf{G}$  and  $\mathbf{H}_t$  are known. The future state can be predicted in terms of the Kalman filter as (Kitagawa and Gersch 1984)

$$\bar{\mathbf{x}}_{t|t-1} = \mathbf{F}\bar{\mathbf{x}}_{t-1|t-1} \quad (6)$$

$$\mathbf{V}_{t|t-1} = \mathbf{F}\mathbf{V}_{t-1|t-1}\mathbf{F}^T + \mathbf{G}\mathbf{Q}\mathbf{G}^T \quad (7)$$

where  $\bar{\mathbf{x}}_{t|t-1}$  and  $\mathbf{V}_{t|t-1}$  denote the predicted conditional mean matrix and covariance matrix at  $t$  under the condition of the state at  $t-1$  respectively.  $\mathbf{Q}$  stands for the covariance matrix of  $\mathbf{v}_t$ . The filtered state also can be estimated as

$$\bar{\mathbf{x}}_{t|t} = \bar{\mathbf{x}}_{t|t-1} + \mathbf{K}_t(y_t - \mathbf{H}_t\bar{\mathbf{x}}_{t|t-1}) \quad (8)$$

$$\mathbf{V}_{t|t} = (\mathbf{I} - \mathbf{K}_t\mathbf{H}_t)\mathbf{V}_{t|t-1} \quad (9)$$

where  $\mathbf{K}_t$  is the Kalman gain defined by Eq. (10).

$$\mathbf{K}_t = \mathbf{V}_{t|t-1}\mathbf{H}_t^T(\mathbf{H}_t\mathbf{V}_{t|t-1}\mathbf{H}_t^T + R)^{-1} \quad (10)$$

where  $R$  denotes the variance of  $w_t$ . This study yields recursive computations for filtered estimates of the state matrix, and calculates predictions and residuals. Prediction at  $t$  ( $\hat{y}_t$ ) are defined by Eq. (11).

$$\hat{y}_t = \mathbf{H}_t\bar{\mathbf{x}}_{t|t} \quad (11)$$

Residuals at  $t$  ( $r_t$ ), difference between the observation and prediction at  $t$ , are defined by Eq. (12).

$$r_t = y_t - \hat{y}_t \tag{12}$$

### 2.2.3 Application to this study

This study adopts  $DI_{ob}$  at  $t$  ( $DI_{ob}^{(t)}$ ) as  $y_t$  and  $DI_{pr}$  at  $t$  ( $DI_{pr}^{(t)}$ ) as  $\hat{y}_t$  respectively. Moreover, this study adopts a time-series model to consider environmental factors defined by Eq. (13).

$$DI_{ob}^{(t)} = \sum_{i=1}^q \alpha_i DI_{ob}^{(t-i)} + \sum_{i=1}^q \beta_i u^{(t-i)} + w_t \tag{13}$$

where  $q$  stands for the model order.  $\alpha_i$  and  $\beta_i$  are model parameters.  $u^{(t)}$  and  $w_t$  denote environmental and operational factors and noise at  $t$  respectively. In other words, this study adopts the following relationships for the parameter and matrixes in Eqs. (4) and (5).

$$y_t = DI_{ob}^{(t)} \tag{14}$$

$$\mathbf{F} = \mathbf{I} \text{ (Identity matrix)} \tag{15}$$

$$\mathbf{G} = \mathbf{0} \text{ (Null matrix)} \tag{16}$$

$$\mathbf{x}_t = [\alpha_1, \dots, \alpha_q, \beta_1, \dots, \beta_q]^T \tag{17}$$

$$\mathbf{H}_t = [DI_{ob}^{(t-1)}, \dots, DI_{ob}^{(t-q)}, u^{(t-1)}, \dots, u^{(t-q)}] \tag{18}$$

$$R = 1 \tag{19}$$

Moreover the initial mean and covariance matrixes can be described as

$$\bar{\mathbf{x}}_{0|0} = \mathbf{0} \text{ (Null matrix)} \tag{20}$$

$$\mathbf{V}_{0|0} = \mathbf{I} \text{ (Identity matrix)} \tag{21}$$

The flowchart of the Bayesian regression analysis to consider environmental changes in this study is shown in Fig. 1.

### 2.3 Decision-making on bridge health condition based on residuals: step 3

Step 3 is to make a decision on bridge health condition based on residuals utilizing 95% confidence interval and the Bayesian hypothesis testing. In the context of bridge health monitoring, we assumed that the residuals follow a normal distribution (Jiang and Mahadevan 2008). The residuals are differences between the  $DI_{ob}$  in the step 1 and the  $DI_{pr}$  from the Bayesian regression in the step 2.

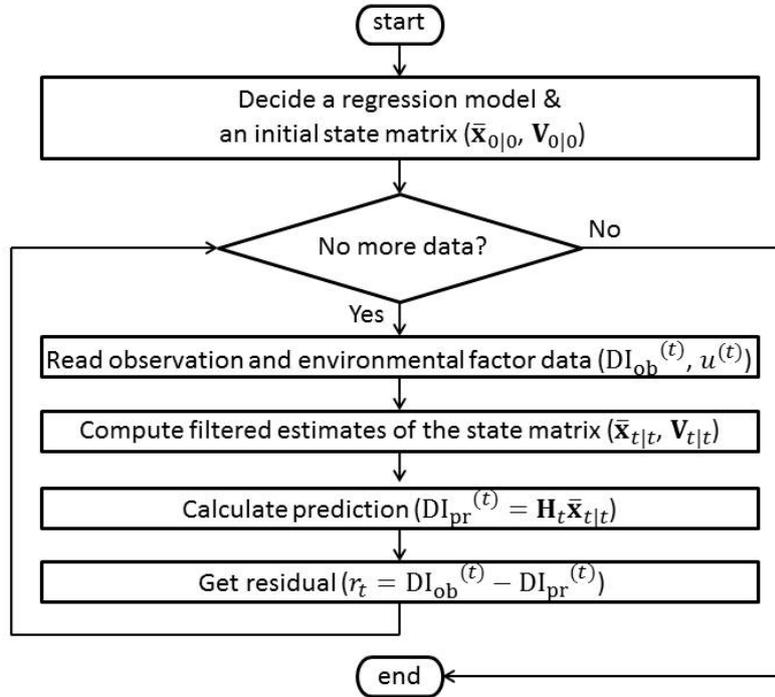

Fig. 1 Flowchart of the Bayesian regression analysis to consider environmental changes

### 2.3.1 Decision-making utilizing 95% confidence interval

This study adopts a fitting probability of the residuals within 95% confidence interval. The threshold for the 95% confidence interval is represented by  $\mu \pm 1.96\sigma$ , where  $\mu$  and  $\sigma$  indicate the mean and standard deviation of the residuals respectively. The 95% confidence interval means that the interval contains 95% of the residuals of observations taken from the healthy bridge. Therefore, if the fitting probability is much less than 95%, there might be some changes in the bridge health condition.

### 2.3.2 Decision-making utilizing the Bayesian hypothesis testing

In Bayesian statistics, it is possible to compute the probability of a hypothesis conditionally on observed data. Quantities that are conditional on observed data are called posterior, and the posterior odds is used for comparing hypothesis as shown in Eq. (22).

$$Post_{odds} = \frac{p(H_1 | \mathbf{D})}{p(H_0 | \mathbf{D})} \quad (22)$$

If the null hypothesis ( $H_0$ ) is defined as ‘healthy’ and the alternate hypothesis ( $H_1$ ) is defined as ‘damage’. The posterior odds are obtained by utilizing priors and marginal likelihoods as follows.

$$Post_{odds} = \frac{p(H_1 | \mathbf{D})}{p(H_0 | \mathbf{D})} = \frac{p(\mathbf{D} | H_1)}{p(\mathbf{D} | H_0)} \times \frac{p(H_1)}{p(H_0)} \tag{23}$$

where  $\mathbf{D}$  refers to the data obtained during monitoring,  $p(H_1)/p(H_0)$  indicates the prior odds, and  $p(\mathbf{D} | H_1)$  and  $p(\mathbf{D} | H_0)$  are called the marginal likelihoods.

We call the ratio of the marginal likelihoods as Bayes factor ( $B$ ), which is defined as the ratio of likelihood of the two scenarios ‘damage’ and ‘healthy’ as follows (e.g., Kass and Raftery 1995).

$$B = \frac{p(\mathbf{D} | H_1)}{p(\mathbf{D} | H_0)} = \frac{\int p(\mathbf{D} | \theta_1, H_1)p(\theta_1 | H_1)d\theta_1}{\int p(\mathbf{D} | \theta_0, H_0)p(\theta_0 | H_0)d\theta_0} \tag{24}$$

where  $\theta_0$  and  $\theta_1$  are parameters under  $H_0$  and  $H_1$  respectively.

If the Bayes factor is greater than 1, it implies that the data favor the hypothesis  $H_1$  and hence suggests that there is damage. If the Bayes factor is less than 1, then there is no damage. According to Jeffreys (1998), a Bayes factor such that  $1 < B < 3$  is ‘barely worth mentioning’,  $3 < B < 10$  is ‘substantial’,  $10 < B < 30$  is ‘strong’,  $30 < B < 100$  is ‘very strong’, and  $B > 100$  is ‘decisive’. In other words,  $B < 1$  is ‘nothing (no damage)’,  $1 < B < 3$  is ‘very small’,  $3 < B < 10$  is ‘small’,  $10 < B < 30$  is ‘strong’,  $30 < B < 100$  is ‘very strong’ and  $B > 100$  is ‘decisive (damage)’. In practical applications, it might provide a threshold to decide an inspection, e.g. an emergency inspection if the Bayes factor gets more than 100 continuously, although more comprehensive studies are needed.

### 3. Long-term monitoring on an in-service plate-Gerber bridge

This study utilizes data monitored at a short span steel girder bridge recorded over a one year period. The seven-span plate-Gerber bridge shown in Fig. 2 is the observed bridge, which is located on a busy national road in Japan. The bridge properties are summarized in Table 1. The plan view with sensor locations on the observation span is shown in Fig. 3. Therein, UA-1, UA-2, DA-1 and DA-2 stand for accelerometers (high sensitivity accelerometers made by Tokyo Sokki Kenkyujo Co., Ltd.) to measure acceleration responses of steel girders on up (UA) and down (DA) lanes. The sampling rate was 200 Hz for acceleration measurements. Thermometers (thermocouple thermometers made by Tokyo Sokki Kenkyujo Co., Ltd.) are denoted by T-5 and T-6. Temperature is measured once every hour. A BWIM system (Moses 1979 and Heng *et al.* 2011) is installed in the bridge, and this study also utilizes the vehicle’s whole weight estimated by the BWIM system.

Table 1 Properties of the observation bridge

Construction year		1960
Bridge length (m)		186.4
Span length (m)	Hanging girder	16.0
	Anchorage girder	40.8
Width (m)		8.0

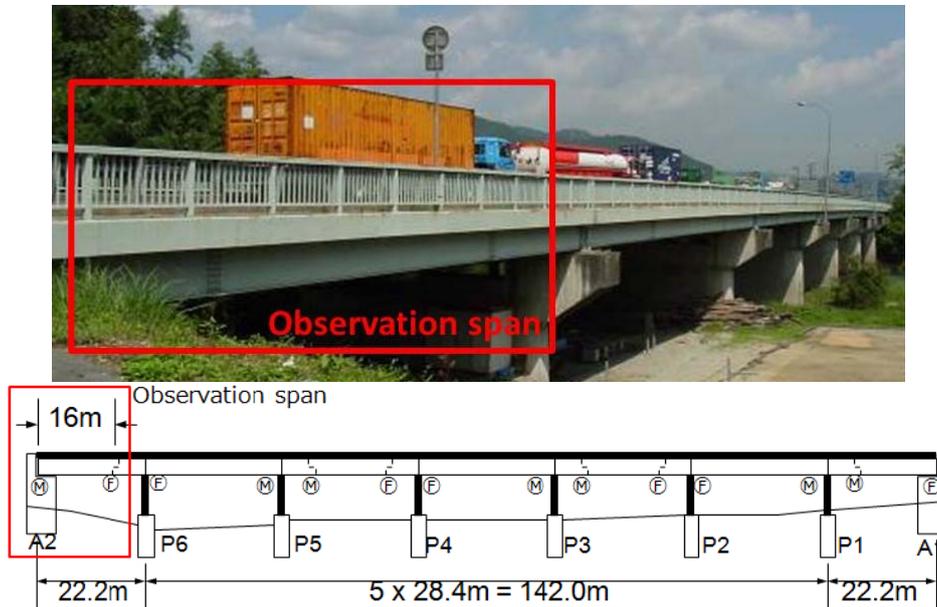

Fig. 2 Observation bridge

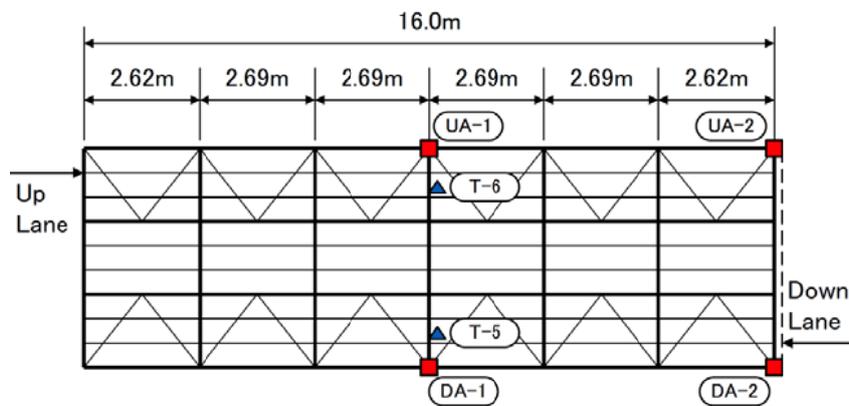

Fig. 3 Sensor locations on the observation span

This study focuses on the effects of time-varying temperature and vehicle weight measured at 7:00, 13:00 and 19:00 on every Wednesday and Sunday for about one year (6<sup>th</sup> August 2008 to 21<sup>st</sup> June 2009); the number of measurements is 276. This study utilized the data measured at 7:00, 13:00 and 19:00 on every Wednesday and Sunday represent the data measured in the morning, afternoon and night every weekday and weekend in order to reduce time consuming data analysis in the context of a preliminary study. A noteworthy point is that all the data is taken from the healthy bridge since no damage and deterioration was reported during the monitoring period.

### 4. Application and discussion

#### 4.1 Regression analysis to consider environmental changes

Three different data combinations summarized in Table 2 are considered to investigate the influence of temperature and vehicle weight as environmental and operational factors: Case 1 is to utilize acceleration, temperature and vehicle weight data considering temperature and vehicle weight as environmental and operational factors; Case 2 is to utilize acceleration and temperature data considering temperature as environmental factor; and Case 3 is to utilize only acceleration data without considering environmental and operational effects.

Table 2 Three cases to consider in this study

	Considered factors	Utilized data
Case 1	Temperature & vehicle weight	Acceleration, temperature & vehicle weight
Case 2	Temperature	Acceleration & temperature
Case 3	Not considered	Acceleration

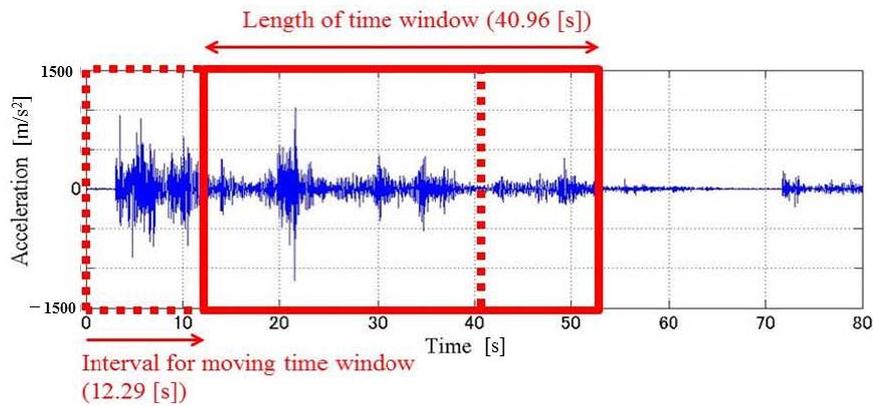

Fig. 4 Time windows to identify the  $DI_{ob}$ 's from acceleration measured at UA-1

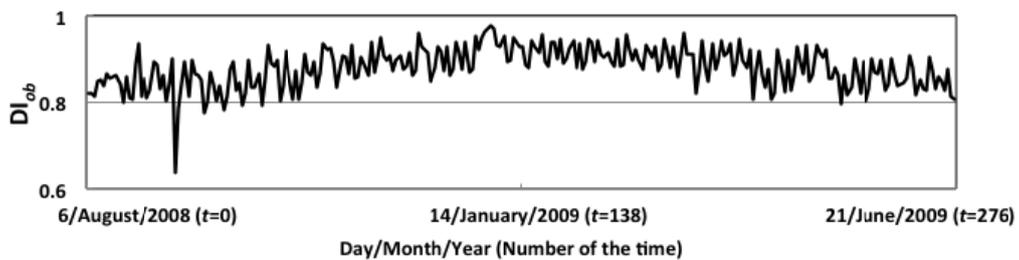

Fig. 5  $DI_{ob}$ 's identified at the sensor of UA-1

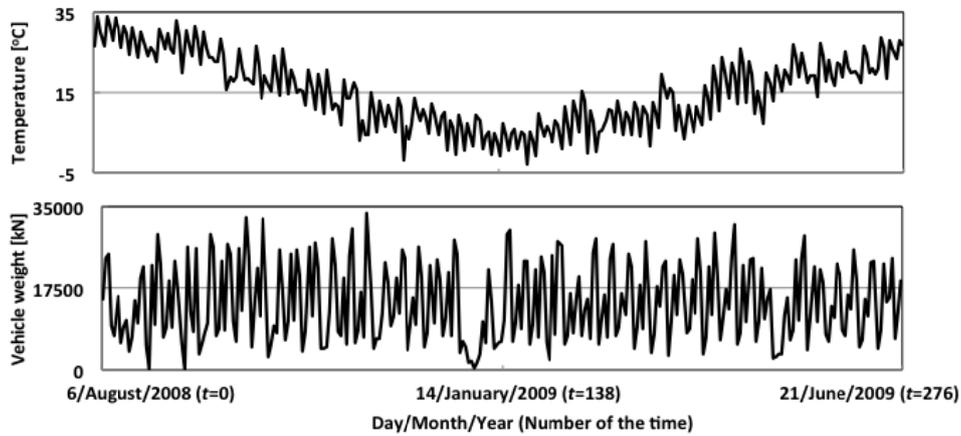

Fig. 6 Temperature measured at the sensor of T-6 and vehicle weight estimated by the BWIM system on up lane

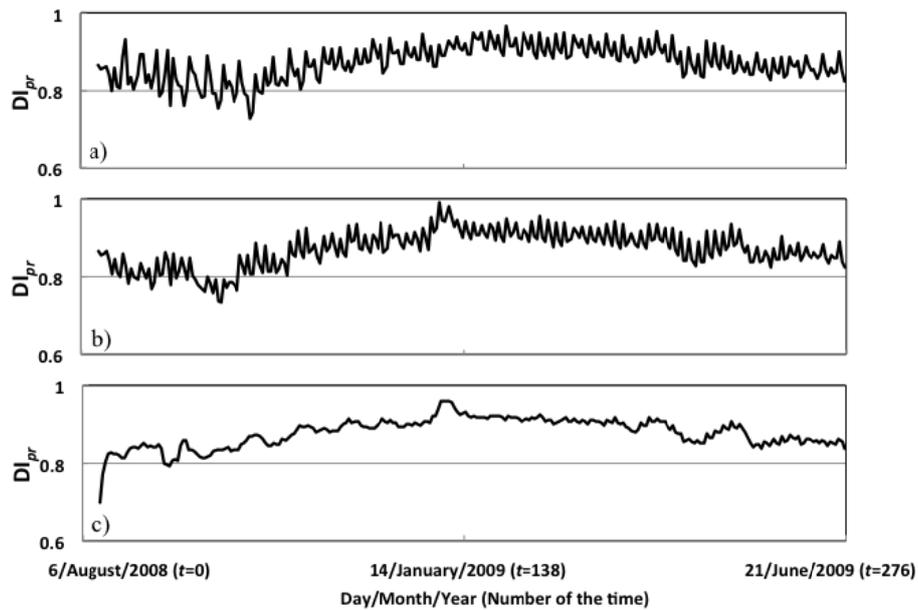

Fig. 7  $DI_{pr}$ 's at the sensor of UA-1 in (a) Case 1, (b) Case 2 and (c) Case 3

This study identifies 100  $DI_{ob}$ 's from blocks of acceleration data obtaining by means of moving time windows as shown in Fig. 4. This study adopted 40.96s as the moving window length following a preliminary investigation considering data 20.48s, 40.96s and 81.92s which showed similar trends with each other. For the overlap window, a moving window with 70% overlap (28.67s, in other words 12.29s for un-overlap window length) was adopted in this study.

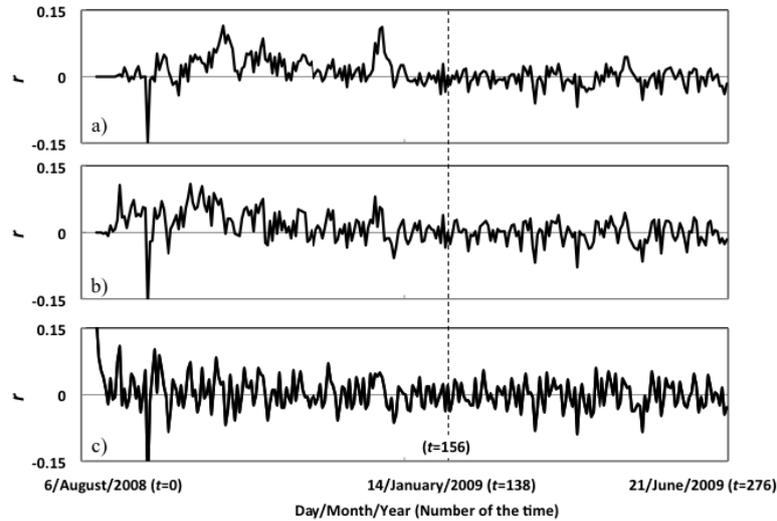

Fig. 8 Residuals at the sensor of UA-1 in (a) Case 1, (b) Case 2 and (c) Case 3

Table 3 Fitting probability of residuals after  $t=156$  in Cases 1, 2 and 3 within 95% confidence interval regarding Case 1

	UA-1	UA-2	DA-1	DA-2
Case 1	95.9%	92.6%	92.6%	93.4%
Case 2	92.6%	92.6%	92.6%	93.4%
Case 3	79.3%	89.3%	93.4%	90.9%

The  $DI_{ob}$ 's identified at the sensors of UA-1 are shown in Fig. 5. The temperature measured at the sensor of T-6 and vehicle weight estimated by the BWIM system on the up lane are shown in Fig. 6. This study considered sums of weights of vehicles traveling on the bridge during the time block that is used in estimating the  $DI_{pr}$ . Changes in the  $DI_{ob}$ 's and temperatures during about one year were about 0.3 and 40 degrees Celsius respectively. Those changes are about 34% of mean  $DI_{ob}$  (0.88) and about 38% of mean temperature (15.18 degrees Celsius). It is also apparent that the lower the temperatures is, the greater the  $DI_{ob}$ 's become.

The potential reason for the  $DI_{ob}$  increase with lower temperature is that the  $DI_{ob}$  has similar feature with frequencies that increase with lower temperature. The changes in the  $DI_{ob}$ 's (even frequencies) depending on temperatures might be caused by changes in the boundary condition at the supports of the bridge caused due to varying temperatures and roller supports that do not function well.

Fig. 7 shows  $DI_{pr}$ 's at the sensor of UA-1 in Cases 1, 2 and 3. Fig. 8 shows the residuals at the sensor of UA-1 in Cases 1, 2 and 3. The residuals converge within bias of  $\pm 0.05$  after about 156 times ( $t=156$ ) elapsed from the start.

Table 3 shows the fitting probability of the residuals after  $t=156$  in Cases 1, 2 and 3 at the sensors of UA-1, UA-2, DA-1 and DA-2. This study adopts the 95% confidence interval of the residuals after  $t=156$  in Case 1 as threshold of the fitting probability. It is found that the fitting probability in Cases 1 and 2 are greater than that in Case 3 at the sensors of UA-1, UA-2 and DA-2.

It demonstrated that the regression analysis considering environmental and operational changes (Case 1) leads to more accurate results than that without considering environmental and operational changes (Case 3). It is also obvious that the fitting probability in Case 1 is greater than that in Case 2 at the sensors of UA-1. It demonstrated that the regression analysis considering both temperature and vehicle weight as environmental and operational factors (Case 1) leads to more accurate results than that considering only temperature as an environmental factor (Case 2), even though the differences are negligible except UA-1 in which UA-1 is located on the entering span of the up lane and easily affected by large dynamic wheel loads of the vehicles activated when the vehicles pass on the expansion joint of the entering span (Kim *et al.* 2007). From this result, it would be reasonable to consider only temperature under condition less affected by passing vehicles.

#### 4.2 Bayes factor for decision-making on anomaly from residuals

As an example of applying the Bayesian hypothesis testing, this study assumes that the null hypothesis is defined by Eq. (25) and the alternate hypothesis is defined by Eq. (26) (Sankararaman and Mahadevan 2011).

$$H_0 : \mu = 0 \quad (25)$$

$$H_1 : \mu \neq 0 \quad (26)$$

where  $\mu$  denotes the mean value of the residual shown in Eq. (12).

This study adopts the equation for  $B$  proposed by Jiang and Mahadevan (2008) shown in Eq. (27).

$$\begin{aligned} B &= \frac{\int p(\mathbf{D} | \mu, H_1) p(\mu | H_1) d\mu}{p(\mathbf{D})} \\ &= \frac{\left(\frac{1}{2\pi\sigma^2}\right)^{\frac{N}{2}} \frac{1}{\sqrt{N+1}} \exp\left(-\frac{1}{2\sigma^2} \sum_{i=1}^N (r_i - \mu)^2\right) \exp\left(-\frac{N\mu^2}{2(N+1)\sigma^2}\right)}{\left(\frac{1}{2\pi\sigma^2}\right)^{\frac{N}{2}} \exp\left(-\frac{1}{2\sigma^2} \sum_{i=1}^N r_i^2\right)} \\ &= \frac{1}{\sqrt{N+1}} \exp\left(\frac{N^2\mu^2}{2(N+1)\sigma^2}\right) \end{aligned} \quad (27)$$

where  $N$  denotes the number of the data and  $r_i$  represents the  $i$ -th residual.

Table 4 shows Bayes factor ( $B$ ) of the residuals after  $t=156$  for Cases 1, 2 and 3. The Bayes factors were  $0 < B < 1$  except UA-1 of Case 1. Therefore, the probability of damage of the observation bridge is 'no damage', which is natural since data from healthy bridge were considered. At UA-1 of Case 1, greater mean values with less standard deviation of the residuals than other cases would result in relatively bigger Bayes factor (see Eq. (27)).

Table 5 shows the means and standard deviations of the residuals after  $t=156$  in Cases 1, 2 and 3. Observations from Tables 4 and 5 show that the greater the mean values with less standard deviation of the residuals led to bigger Bayes factors.

Table 4 Bayes factor of residuals after  $t=156$  in Bayesian hypothesis testing in Cases 1, 2 and 3

	UA-1	UA-2	DA-1	DA-2
Case 1	1.26(very small)	0.10(no damage)	0.11(no damage)	0.13(no damage)
Case 2	0.17(no damage)	0.09(no damage)	0.14(no damage)	0.16(no damage)
Case 3	0.13(no damage)	0.16(no damage)	0.11(no damage)	0.10(no damage)

Table 5 Mean values and standard deviations of the residuals after  $t=156$  in Cases 1, 2 and 3

	UA-1		UA-2		DA-1		DA-2	
	$\mu$	$\sigma$	$\mu$	$\sigma$	$\mu$	$\sigma$	$\mu$	$\sigma$
Case 1	-0.0042	0.020	-0.0013	0.038	0.0012	0.020	0.0027	0.034
Case 2	-0.0025	0.024	-0.0010	0.042	0.0017	0.021	0.0035	0.035
Case 3	-0.0025	0.030	-0.0045	0.047	0.0012	0.021	0.0014	0.038

## 5. Conclusions

This study investigated a way to consider changes in temperature and vehicle weight as environmental and operational factors for long-term vibration-based BHM by applying a Bayesian approach to long-term monitoring data on an in-service plate-Gerber bridge. The Bayesian approach consists of three steps: step 1 is to identify damage-sensitive features from coefficients of the AR model utilizing bridge accelerations; step 2 is to make a regression analysis of the damage-sensitive features to consider environmental and operational changes by means of the Bayesian regression; step 3 is to make a decision based on the residuals utilizing 95% confidence interval and the Bayesian hypothesis testing. Observations through this study could be summarized as follows.

- (1) The Bayesian regression considering environmental and operational changes led to more accurate results than that without considering environmental and operational changes.
- (2) Regression considering only temperature change was comparable with the regression considering changes in temperature and vehicles on the bridge. From this result, it could be concluded that considering only temperature as an environmental factor would be useful in vibration-based long-term monitoring.
- (3) In the Bayesian hypothesis testing utilizing data from the healthy bridge, the damage probability of the bridge was judged as no damage. However greater mean values with less standard deviation of residuals led to a bigger Bayes factor, which suggests further investigations on establishing a proper hypothesis, for instance " $H_0: \mu=0\pm\Delta$ " where  $\Delta$  denotes a bias of mean residuals, etc.

## Acknowledgments

This study is partly sponsored by JSPS, Grant-in-Aid for Scientific Research (B) under project No. 24360178. Such financial aids are gratefully acknowledged.
